ASTRONOMICAL OBSERVATIONS

MADE AT

THE ROYAL OBSERVATORY, EDINBURGH.

By CHARLES PIAZZI SMYTH, F.R.SS. L. & E., F.R.A.S., F.R.S.S.A.,

CORRESPONDING MEMBER OF THE ACADEMIES OF SCIENCE IN MUNICH AND PALERMO, HONORARY MEMBER OF THE INSTITUTION OF ENGINEERS IN SCOTLAND, AND THE EDINBURGH PHOTOGRAPHIC SOCIETY, PROFESSOR OF PRACTICAL ASTRONOMY IN THE UNIVERSITY OF EDINBURGH, AND ASTRONOMER-ROYAL FOR SCOTLAND.

The Royal Observatory, Calton Hill, Edinburgh.

VOL. XIII. FOR 1860–1869.

WITH ADDITIONS TO 1871.

Published by Order of Her Majesty's Government.

INTRODUCTION TO VOL. XIII.

NOVEMBER 1871.

(1.) THE ROYAL OBSERVATORY, Edinburgh, is situated on the Calton Hill, in the North-eastern quarter of the city, or between Edinburgh and its sea-port of Leith, in Latitude North 55° 57′ 23·2″ (by Mural Circle observation), and in Longitude West of Greenwich 12^{min} $43{\cdot}05^{sec}$ of time (by electric telegraph observations of star-transits in concert with Greenwich). The height of the floor is 348·6 feet above the mean level of the sea in the Firth of Forth near Leith, and the Variation of the Compass (as measured in October 1871, with a borrowed needle) is 22° 46′ West, nearly. *See Plate* 10 *at the end of the Volume.* Situation of Royal Observatory, Edinburgh.

(2.) The chief instruments of the Observatory are an 8-foot Transit Instrument and a 6-foot Mural Circle: their supporting piers, of Craigleith sandstone, are founded at once on the earth-fast porphyritic trap-rock which, after having in geological ages pushed through the surrounding beds of carboniferous sandstone, now forms the summit of the Calton Hill. Supplementary to the above leading instruments (already described as to their details in former volumes) there is a train of Sidereal clocks under electric control of one governing clock kept in a dark closet of approximately uniform temperature. There is also a train of electrically controlled Mean Time Clocks, of which the governing clock is daily adjusted to the tenth of a second, extending from the Observatory over the city of Edinburgh, and including in their course a Time-Ball on Nelson's Monument, and a Time-Gun at the Castle, for daily time-signals at 1 o'clock to the public, besides a special controlled clock at the General Post Office, North Bridge, which clock is made a second Edinburgh centre for distributing the true time as found daily by star observations taken in the Observatory. There is likewise, under a small Dome originally built for an altitude Azimuth Instrument, an apology for an Equatorial, soon however to be replaced by a powerful example, or a reflecting Equatorial of large aperture and short focal length, by Mr Howard Grubb of Dublin: and there is further, outside the building, a set of deeply sunk rock-thermometers for physico-meteorologic observations. Instruments of the Observatory.

(3.) The personal establishment consists of an Astronomer, nominally connected with an honorary Professorship in the University of Edinburgh, and two Assistant Personal Staff of the Observatory

Astronomers. The first of these assistants is Mr Alexander Wallace, M.A., who has held the post most creditably since 1834; and the second is Mr J. Walter Nichol, appointed in December 1870; his predecessor, Mr Peter Williamson, having resigned in the spring of the same year.

Work of the Observatory.

(4.) The work of the establishment consists in keeping up the observations, computations, printing, and general service of the various instruments already enumerated; besides computing the bi-diurnal observations made at 55 Meteorological Stations connected with the Meteorological Society of Scotland, and furnishing the results ready for immediate printing to the Registrar-General of Births, Deaths, and Marriages in Scotland, in whose Monthly and Quarterly Reports they are accordingly printed with eminent punctuality and despatch. There are also, at uncertain intervals, and as exigencies in the progress of science may require, special researches, examinations, or correspondence entered into by the Astronomer, and pursued to the utmost extent of his available means, ability, and time.

General Arrangement of Vol. XIII. of the Edinburgh Astronomical Observations.

(5.) The present volume, XIII., is intended to record all the original observations of more paramount interest made by the personal staff of the Observatory from 1860 to 1869, with some additions in 1870 and 1871. But though the volume is thus a large and collective one, the exhibition of the results of star observations with Meridian Instruments, always the principal work of this Observatory, has been given in distinct annual sections following each other year after year, in the same order and almost precisely in the same manner of treatment, as commenced by the first Astronomer-Royal for Scotland, the late Prof. Henderson, in his separate annual volumes. In our present thick volume, therefore, the purely astronomical portions for all the years included holds the first place, and represents finally about 11,000 star places in Right Ascension and 6000 in Polar Distance. Then came the physico-meteorologic observations of the rock-thermometers to the extent of 2600, with notices of a discussion of previous observations of them from their commencement in 1837, to the extent of 8400 observations altogether; and then the general Meteorologic results deduced by our staff in this Observatory, from observations by the Meteorologic Society of Scotland, to the extent of over 7 millions of such observations. These are followed by upwards of 100 pages of closely printed measures taken in his Great Pyramid research of 1865 by the present Astronomer; and the volume is concluded with the historical portion of the Observatory's affairs or the series of Reports and sometimes separate Memoirs presented by the Astronomer to the Board of Visitors at their several successive Visitations of the Observatory during the interval which has elapsed since the publication of our last volume in 1864.

POSITIONS OF THE TRANSIT INSTRUMENT,

1860–1869.

Together with the position of the Transit axis in level, and in azimuth, is here joined the position of the telescope with reference to the axis—or the error of collimation,—as that is deduced by the same observations of place of the middle wire by reflexions in the Mercury trough, wherefrom the level error is ascertained.

The azimuth error is determined by Polar and equatorial stars, but connects itself in the inquiry with the other two errors, as it refers to another element of the position of one and the same axis.

Before commencing the reductions of observations from 1860 to 1869, a general examination of the ascertained instrumental corrections was made for the period 1849 to 1859 inclusive, as per published observations; and the details are given further on. These showed that the collimation error is, excepting when pointedly disturbed artificially, very nearly constant: but that the level error has an annual cycle of 0·29 sec. = 4·35″; and the azimuth error of 0·64 sec. = 9·60″; and also that there is a march from year to year, or a probable cycle of many years, dependent mainly, but not always very closely, on the mean-temperature variations of the same years.

It is further found that the date of the annual maximum for Level is later than for Azimuth; the former being on August 1, and the latter on June 30. And it is found that the *variations of range* are no less than nine times greater in Azimuth than in Level.

Now, all these features are extremely similar to those which I detailed in Volume VII. (or that for 1841) pp. 86 to 100, as characterising the instrument in my predecessor, Prof. Henderson's, time; and when, by taking the proportion of wave area for each half of the year, from a curve of the quantity dealt with in connection with the time, it was shown how far, comparatively, the apex of maximum was thrown later in the year than the middle of the same by the increase of the second number of the proportion; as thus,—

t_1 or temperature of rock 3 feet deep, ...	1 : 1·941
t_5 or surface temperature of rock, ...	1 : 1·639
Thermometer attached to Barometer, ...	= 1·220
Thermometer in air outside, ...	= 1·114
Level correction of Transit Axis, ...	1 : 1·276
Azimuth correction of do., ...	1 : 1·040

From these numbers, assisted by the accompanying feature of the daily variations

being *greater* in each case, accordingly with the *decrease* of the second proportional number,—I arrived then for both azimuth and level at the same conclusion as my predecessor had previously done for the level alone; or, that the cause of the instrumental variations was *temperature*, and that the medium through which it acted could not possibly be anything connected with the rock of the general hill, and least of all as acted on by sunshine more on the Western side, 100 feet distant, than the Eastern side, 300 feet distant or more,—as often advanced by several respectable citizens—but that it must be something small, easily affected by variations of heat, and located both *within the observing room*, and *above the floor*.

I then pitched on a rather unscientific arrangement of the adjusting screws in the Y bearings, as probably the cause; and was enabled soon after (or in 1848) to have these adjustable bearings removed, and un-adjustable bearings, formed of very large slabs of cast-iron substituted for them. Mounted on these, the instrument certainly proved itself, at many and many a reversal, to be far steadier and more trustworthy than before,—but the principal fluctuations of position produced by temperature have re-appeared, very nearly the same in actual amount as previously, and with many of the same characteristic features both in level and azimuth as in earlier years.

What then is, after all, the agency through which the temperature acts; for temperature it is, we may now say, even more certainly than before, both on the strength of the law of march of many years, as well as the cycle, often repeated, of a single year? An effect too, in its damaging quickness of action, in the azimuthal direction more especially, which it would be exceedingly important to the character and prestige of a first-class Meridian instrument, to get rid of in actual and original fact, if possible.

Lamp experiments were accordingly tried, and are detailed below, showing that these stone piers (though thickly painted) are strangely sensitive to very small portions of radiant heat from mere culinary sources. They seem indeed to drink it in almost as a sponge does water; and the excessive character of the azimuth disturbances is owing to one *side* of a pier being warmed up sooner than the other, and then throwing the whole pier, that should be vertical, slantingly out of that position; carrying the axis of the transit with it, and thereby deviating it most in azimuth.

This, then, is the fault, viz., piers, whose sides are, paint excepted, bare and ready to be influenced by any source of heat, even a little hand-lamp; and whose shape is such as to exaggerate on their summits, the effect of any alteration in the length of their sides.

The data whence the preceding conclusions are drawn are given below in the following tables, whose contents may be thus succinctly described:—

(1.) Weekly observations both of temperature (in degrees Fahrenheit) in earth at 5 different depths and in air, as well as of the positions of the Transit axis (expressed in seconds of time or 86,400 to the circle) for each week in the year 1841. The whole to be regarded as the history of a year touching the positions of the Transit Instrument and temperature with the ancient *adjustable* Y bearings.

Digitized by Google

(2.) Weekly observations both of temperature (in degrees Fahrenheit) in earth at 5 different depths and in air, as well as of the positions of the Transit axis (expressed in seconds of time or 86,400 to the circle) for each week in the year 1850. The whole to be regarded as the history of a year touching the positions of the Transit Instrument and temperature with the present *un-adjustable* Y bearings.

(3.) The Transit positions and Earth temperatures at two depths for every month in each year, year after year from 1849 to 1859.

(4.) Collective view of the mean annual amounts and annual ranges both of Transit positions and Earth temperatures from 1849 to 1859.

(5.) Transit positions and Earth temperatures at two depths arranged in Months, from 1849 to 1859.

(6.) Collective view of Mean monthly amounts and monthly ranges of both Transit positions and Earth temperatures at two depths for the period 1849 to 1859.

(7.) Transit positions and Earth temperatures at two depths for every month in each year, year after year from 1860 to 1869.

(8.) Collective view of mean annual amounts and annual ranges of both Transit positions and Earth temperatures at two depths, year by year from 1860 to 1869.

(9.) Transit positions and Earth temperatures at two depths arranged in months from 1860 to 1869.

(10.) Collective view of Mean monthly amounts and monthly ranges of both Transit positions and Earth temperatures at two depths from 1860 to 1869.

(11 to 16.) Experiments as to the effects of hand lamps and gas-lights in altering the level correction of the Transit piers.

(17 to 18.) Experiments as to the effects of hand lamps in altering the azimuthal position of the Transit piers.

(19.) Experiments as to the effect of measured weights pulling horizontally in disturbing the azimuthal position of the Transit piers.

(20.) General results of the lamp and weight experiments, in altering the level correction and azimuthal adjustment of the Transit piers.

The contents of several of these Tables are further exhibited to the eye in a series of plates at the end of the volume, where

Plate 1 represents Table 1; or gives the history week by week of a year of Transit positions and earth temperature at five depths with the air temperature, for the year 1841, or when the Transit Instrument was still in its ancient *adjustable* screw bearings.

Plate 2 represents Table 2; or gives the history week by week of a whole year of Transit positions and earth temperatures at five depths with the air temperature, for the year 1850, or after the Transit Instrument was established in its present *non-adjustable* bearings.

In both these plates it will be seen that the azimuthal variations of the Transit instrument are larger than its level variations: that they both follow the law of temperature: not so rapidly or with such violent weekly variations as the air, or even the 3 inch deep earth thermometer, but more quickly than the 6, 12, or 24 French feet deep thermometers.

But on contrasting these plates with each other, it will be seen that the weekly variations of Transit position have been rather notably reduced in the second case by the adoption of the non-adjustable Y bearings, though the general amount between summer and winter is nearly what it was before.

Plate 3 represents part of Table 4, or gives the law of the annual march, on a mean of 11 years from 1849 to 1859, of the Transit positions, Air temperature, and Earth temperature at two depths, viz., 3 inches and 3 feet.

The most important feature to be remarked here is the *date* at which each fluctuation and temperature arrives at its respective maximum. The level being later than the air, and 3 inch earth temperature, but not so late as 3 feet earth temperature: while the azimuth is actually earlier than even the air temperature, and is due to its being produced by the first heats of early summer acting on the more expansible sides of the piers skin deep only—for, when the heat has had time to transfuse itself through the whole substance of the pier, level error is then its chief effect.

Plate 4 represents that part of Table 4, which gives the ranges of both instrumental

Digitized by Google

and temperature fluctuations from 1849 to 1859; and shows that over and above this mean temperature of a month, the *range* of temperature in the same time has an effect of its own on the fluctuations in position of the Transit axis, and far more notably in the azimuthal, than the vertical direction.

Plate 5, gives from Table 7, the history of the mean annual positions and mean annual temperatures from 1849 to 1869, showing, with some intermediate anomalies and these chiefly in azimuth, yet still pretty well proving by the concluding years that no particular alteration from any cause except temperature has acted on the Transit piers during the long space of 21 years; or that at least they are safe from any unequal sinking or twisting on their foundations in the cumulative manner too common in other Observatories, where their piers are founded on soft soil, pervious to water.

Plate 6 gives the history of the same 21 years from 1849 to 1869 as regards the effect of *range* of temperature in each year, as distinct from the absolute mean temperature, in producing *ranges* of instrumental fluctuation of position.

Plate 7 represents from Tables 11 to 16 six experiments with artificial lights, as to their power by radiant heat to increase the height of one transit pier over the other, or produce "level error." At the beginning of 5, out of the 6, experiments it will be observed that there is a negative effect: that arises from the *first* effect of the artificial heat, applied in those cases near the bottom of the pier, being to produce azimuthal disturbance or to throw the pier out of the vertical and thereby shorten its vertical height which is what the level actually measures. In the one and only case where such negative effect is not perceived, the heat was applied at the top of the pier.

Plate 8 represents from Table 17 a series of further measures taken during the application of artificial heat to ascertain the disturbances produced *simultaneously both on the level and the azimuth* of a transit pier; and they confirm the previously expressed conclusion that the first negative effect in the level is accompanied by an extra amount of effect in azimuth. At the foot of this plate are also shown the results of applying weights to pull the tops of the piers out of azimuthal position: and when the weights were removed, the piers sprang back so decidedly up to, if not beyond, their first position, as to show that the fixing of the base of the piers to their foundation rock must be very perfect.

Plates 9 and 10 are mainly intended for other portions of the volume; but will serve also in this,—the former, to testify to the continually varying amounts of temperature modified by the part of the Observatory or instruments being acted on; and the latter to illustrate the general position of the Observatory, and especially of the rock-thermometers which have proved so useful in this inquiry, on the top of the Calton Hill.

EXPERIMENTS ON THE TRANSIT PIERS.

ARTIFICIAL HEAT.

In January 1862 experiments were made with artificial heat on the piers of the Transit Instrument, and were directed first towards producing a difference of level of the axis, by placing several lamps near the piers; the effects of the heat of such lamps, if any, being measured by the displacement of the wire in the collimating trough, or by alteration of the tabular level error of the day. The observations were generally conducted in the middle and after part of the day, and did not sensibly disturb the temperature of the observing room as a whole.

TABLE XI.

Experiment 1; *on January* 1.

Placed 8 small hand-lamps on a stool 2 feet high, and 8 inches distant from South side of *West* pier, and obtained the following results at the specified successive times,—

	h.	m.		Level corrections. sec.	Lengthening of height of pier. sec.	Interval from lighting. h. m.
Sid. Time	19	40	before lighting	+·174	0	0
	20	10	lit lamps	...	0	0

	2 25	...	+ ·199	+ ·025	5 30
	2 40	...	+ ·199	+ ·025	5 45

TABLE XV.

Experiment 5; *on January* 8.

Lit the same gas-lantern in the same place, but took off glass and opened door, to let flame radiate freely on pier.

	h. m.		Level corrections. sec.	Lengthening of height of pier. sec.	Interval from lighting. h. m.
Sid. Time	20 45	before lighting	+ ·156	0	...
	20 50	lit up gas	...	...	...
	21 0	...	+ ·152	− ·004	0 15
	21 15	...	+ ·152	− ·004	0 30
	21 30	...	+ ·158	+ ·002	0 45
	21 45	...	+ ·160	+ ·004	1 0
	22 0	...	+ ·163	+ ·007	1 15
	22 15	...	+ ·165	+ ·009	1 30
	1 0	...	+ ·167	+ ·011	4 15

Now all these experiments, excepting the 3rd, agree together in making the first effect of the lamp-heat to shorten the height of the pier; though afterwards the height was most unmistakably increased.

To what could this apparently unnatural effect be owing? Probably to this, that the heat being applied to one side of the pier, that warmed up first, elongated, and from the tall shape of the pier threw it so far out of level, here in azimuth, as to shorten its vertical height; but as time went on, the heat of that one side would be gradually conducted through the substance of the pier, the pier would then straighten up, become more nearly vertical, and would then show the increased length it had acquired from its acquisition of temperature.

If this be true, by placing lamps on *either* side of the pier, in place of one side only, we should be able to reduce the azimuthal deviation or first shortening, and increase the subsequent lengthening. This experiment was accordingly tried on January 16.

TABLE XVI.

Experiment 6; *on January* 16.

Placed 4 hand-lamps on stools, on *either* side of lower part of East pier, and within a few inches of it.

	h.	m.		Level corrections. sec.	Lengthening of height of pier. sec.	Interval from lighting. h. m.
Sid. Time	21	0	before lighting	+·169	0	...
	21	2	lit up	...	...	...
	21	7	...	+·159	−·009	0 5
	21	12	...	+·159	−·009	0 10
	21	17	...	+·166	−·002	0 15
	21	22	..	+·170	+·002	0 20
	21	27	...	+·172	+·004	0 25
	21	32	...	+·177	+·009	0 30
	21	37	...	+·177	+·009	0 35
	21	42	...	+·179	+·011	0 40
	21	47	...	+·179	+·011	0 45
	22	0	...	+·181	+·013	0 58
	22	30	...	+·194	+·026	1 28
	23	30	...	+·240	+·072	2 28
	0	30	...	+·265	+·097	3 28
	1	19	...	+·287	+·119	4 17

Hence accordingly we find that the first shortening is less than in Experiments 1 and 2, but the after lengthening is nearly four times as great; it remains therefore only to investigate what occurs in the Azimuthal position of the axis, when such changes are going on in level. It being premised that in the one only negative experiment, or No. 3, such effect is explainable there by the heat acting at the top only of the pier (not near the bottom as the others) and being taken quickly across that top by the metal plates covering it.

Digitized by Google

TABLE XVII.

Experiment 7 ; *on January* 11.

On January 11, therefore, five hand-lamps were placed on South side of West pier, 3 feet from the ground, and four inches from the pier ; the effect on the level of the axis was tested as before by micrometer measures of the reflected image of the wire in the Mercury trough ; and on the azimuthal position by micrometer measures of the South collimating mark, not far from a horizontal direction.

Times Sid. T.	Act.	Level corrections.	Alteration of height of pier.	Azimuthal corrections.	Alterations of Az. pos.	Interval of time from lighting
h. m.		Sec.	Sec.	Sec		h. m.
20 30	Before lighting	+ ·143	...	...	...	...
20 32	...	...	...	+ ·430	...	...
20 35	Lit up lamps	...	...	...	...	...
20 45	...	+ ·134	− ·009	+ ·397	+ ·033	0 10
21 0	...	+ ·141	− ·002	+ ·393	+ ·037	0 25
21 15	...	+ ·152	+ ·009	+ ·320	+ ·110	0 40

23 0	...	+ ·174	+ ·031	+ ·140	+ ·290	2 25

Here the level effect shows its accustomed law of first slightly negative, afterwards increasingly positive ; but the azimuthal effect knows no such preliminary contradiction and attains to nearly 10 times the effect of the level disturbance. This matter was tried again in

TABLE XVIII.

Experiment 8 ; *on January* 13.

In this experiment the level of the axis was determined separately before and after the heat experiments for azimuth, and was found to have changed through no more than 0·024 sec., while the azimuthal position had changed nearly 20 times that amount. There were four hand-lamps placed within 6 inches of the S. side of East pier, and the same number similarly with regard to the N. side of West pier. Readings of the collimating marks, both N. and S., were obtained both before and again some two hours after the lighting of the lamps, with the result that the North mark had decreased by

Sec.
0·463,

and the South mark increased by Sec. 0·440 ;

Mean = Sec. 0·452,

or nearly 20 times the amount of Level alteration.

TABLE XIX.

Experiment 9 ; *on October* 27, 1869.

To ascertain the mechanical force exerted by the lamps, cords were put round the upper part of the transit piers, about 4 inches under the iron plate-caps, and weights hung from the said cords over pulleys specially put up on the neighbouring steps for the

occasion. One weight of 28 lb. or A, was arranged to hang on North side of West pier, pulling its top towards the North; and another 28 lb. weight, or B, was arranged to hang on the South side of the East pier. Their effects were thus cumulative; and they did pull round the telescope tube azimuthally in the way intended, and by the amounts given below; but when the weights were removed the piers sprang back again, at least to, possibly a little beyond, their first position unacted on by any weights.

		Sec.	Effect.	Sec.
Reading for Collimating mark, no weights at all being applied, ...	=	334		
,, weight A applied, . .	=	387	28 lb. =	+·053
,, weight B also applied, .	=	436	56 lb. =	+·102
,, weight B off again, . .	=	374	28 lb. =	+·040
,, weight A also taken off, or free position of instrument, ...	=	326		

TABLE XX.

General Results of the Lamp and Weight Experiments.

		Sec.
Hence (1) four lamps on either side of one pier have increased its height	=	·119
(2) but placed on alternate sides of opposite piers they have altered the level inappreciably, but the azimuth by		·452
(3) one 28 lb. weight on the opposite side of each pier, or a pull of 56 lb. on both, has altered the azimuth by		·102

and the uncertainty of any one of these determinations is probably under ·005 sec.

Conclusions deduced.

Now the effect of the same lamps being four times as great in producing error of azimuth, or level error, when arranged suitably for each, and also producing generally, when arranged for level effect only, a *preliminary* disturbance in azimuth, is similar to the observed effect of atmospheric temperature, where the azimuth range is more than twice as great as the level range, but the *variation* of the azimuth range is more than seven times as much (see p. xiii) as the variation of the level range; while the azimuth disturbance again arrives at its culminating point earlier than the level correction, or on June 30, in place of August 1. (See Plate of curves, No. 3).

When we further compare these dates of culmination of either error with the dates of culmination always later in the year, of any of the rock thermometers (see Tables 1

Digitized by Google

and 2), it is abundantly plain that neither the rock of the hill nor anything under the floor of the Observatory is at fault, but the piers; and with them it is that portion of them above the floor only which is concerned. Indeed there sixteen little hand-lamps at a few inches distance will in one hour disturb the position of the transit-axis (by expanding the stone piers on which it rests) through the amount of the whole annual variation between winter and summer; while a pull of 336 lbs. on the top of pier will produce an equal effect instantly. But as that effect is one of which it would be desirable that not $\frac{1}{50}$th part should go undiscovered or uncorrected, it is evident that even a single small lamp put down temporarily near one of the piers may practically derange it.

ABSOLUTE AMOUNT OF THE CHANGES.

Can then the piers in future be so arranged or improved as to avoid or cure these perplexing and never-ending troubles? Let us inquire by means of the level error. The mean annual effect for 10 years is 0·29 sec. = 4·35 seconds of space, and arises from a mean annual range of air temperature of about 20° Fah., acting so as to produce a *difference* of length on two pieces of stone, the piers, masses about 80 inches high, and 42 inches asunder. Such difference of length will amount to ·0009 inch. Now the expansions of various substances selected from Baily's Tables, are for 20° and 80 inches of length as follows:—

	Inch.	Diff.
Least expansible glass	= 0·0069	·0013
Most " "	= 0·0082	
Least expansible iron	= 0·0099	·0013
Most " "	= 0·0112	
Least expansible brass	= 0·0153	·0019
Most " "	= 0·0172	

Hence even if we had had both piers made equally to the eye, and to ordinary tests either of glass, iron, or brass—there might have been still greater differences of heat expansion than what we have actually found.

PHYSICAL NATURE OF THE STONE CONCERNED.

On the other hand, however, the Craigleith sandstone composing the piers, is by no means among the best of the natural stones that might have been employed, and for the following reasons: 1*st*, Its expansion from heat is said (though perhaps on old and coarse experiments requiring repetition) greatly to exceed that of most other stones, especially limestones, and to come nearer to cast-iron; 2*nd*, It is more easily enterable by, and permeable to, heat, as proved by Principal Forbes' discussion of the earth-thermometer observations at the Craigleith Quarry and the Experimental Gardens, as compared with the similar set in the trap-rock of the Calton Hill. And 3*d*, there are very abnormal patches of iron oxide in the Craigleith stone. A better physical nature of stone might therefore without doubt be selected.

A better shape might also be given to the pier. The azimuth correction being one which we have no mechanical means here of inquiring into during observations, ought to be the most secure and constant of the whole of the corrections which transit-instruments are liable to; and towards that end the piers should evidently be longer in the Meridian direction than they are high; or, keeping their present height, they should be extended North and South, decidedly into the shape of *Meridian walls.* The slabs of stone, too, in place of being set up vertically like wooden posts, should be laid with their stratification horizontal, or as they lay in the quarry; and finally, the shape of the stonework under the floor should be such, that while the observer has the present space between the two piers above the floor, the pivots of the transit axis should rest vertically over the centre of the base of the stone pillar on the rock, and not on the inside edge of it as at present.

As a further protection from radiant heat, and to insure the effects of nothing else than shade-temperature, the surfaces of the piers should evidently be gilt, and surrounded by thin gilt casings, between which and the pier air should be made to circulate spirally.

These subjects, with some further detail, were brought before the attention of the Board of Visitors on June 29, 1870, and I hope may induce them to apply for the necessary allowance to enable some practical steps of physical enquiry to be taken, and then of mechanical improvement to be made, on the instrument for the future. Meanwhile for the present volume, or the years 1860 to 1869, the usual tables will be given at the end of each year's observations of the daily amounts of correction concluded for the Transit Instrument in Collimation, Level, and Azimuth, and applied to the observations in the manner practised hitherto.

TRANSIT CLOCK,

1860–1869.

At the beginning of this period, 1860 to 1869, the Transit Clock, on its old pier nearly under the breezy and drafty Meridian openings of the roof, having been surrounded by a second case to "slow" and decrease changes of temperature on the pendulum, the Transit Clock, never a loud beater, became so nearly inaudible as to its seconds ticks, that advantage was taken of the clock having a contact breaker already applied to it, to work certain electro-magnets and their keepers, in a form contrived for the purpose and called by us "electrical rappers," to rap out the seconds loudly.

These were varied from time to time, even to employing a frame carrying two tambourines upon which a very light drum-stick was worked by the electro-magnets, but always with the effect of finding that electricity should, if possible, only be employed to communicate an order, not to execute it if that execution requires the movement of any sensibly sized material masses. Hence we were led by our own experiments gradually into the principle of R. L. Jones' patent electrically controlled clocks, where each clock is in the first place driven or worked mechanically by a weight wound up by muscular power, and then the *rate* only at which such clock goes is looked to, or regulated, by the electric force employed.

In the month of April 1861, therefore, we began to employ Mr Jones' method of controlling clocks, both Sidereal Clocks in the Observatory and Mean-time Clocks in the city, one of them being at the Castle in connection with the Time-gun.

The original or Governing Sidereal Clock was also now moved away into a large closed closet on the south (but not an external) side of the centre-room of the Observatory, for the sake of keeping it at a more equal temperature; and, in its old place near the Transit Instrument was erected, with Mr Jones' assistance, a huge Turret clock, showing by means of the electric control the same time as the original fine Dent's clock in the closet, but capable of beating the seconds with an unprecedented force of its own, or mechanically about 1000 times greater than that of the fine-clock.

This great Seconds-beating clock has since been termed the "Observing Clock," and is now a chief feature of the Meridian portion of the Observatory.

In order that the observer may *see* the time easily, the clock face is large (22 inches in diameter), and that it may not spoil the eye of the observer for seeing faint blue stars is both painted red, and illuminated at night through a red-glass; but, more important still, that the observer may *hear* the seconds ticks in the clearest possible manner, the seconds are struck by a little hammer on a wooden tambourine *outside* the clock-case, and may be heard all over the Observatory.

The general result therefore at the end of these ten years of experiments is—that in

place of a small-faced fine clock, beating almost inaudibly and exposed, with danger to its rate, to rushes of air and rapid changes of temperature, for our Transit Observing Clock —we have now visibly a large clock beating the seconds if necessary so loudly as to overpower all other noises, and totally uninfluenced in its rate by any sudden changes of temperature or rushes of air which may occur to it, because its rate depends on another clock, in another place and concealed in a dark closet.

This method may be still inferior for the highest accuracy to the *contact* method of both observing and recording by *chronograph*, if the governing clock there be also in a closet; but wherever the method of observing by eye and ear combined is still adopted, there is no doubt that our arrangement in 1869 is incomparably more easy, pleasant, accurate and powerful than what we were following in 1860, and which it is believed many other Observatories are using still.

As already indicated, we did not arrive at full perfection by any means on our first essay at alteration; but, on the contrary, met with many troubles which were only slowly overcome. Amongst these the following may be mentioned as tending to save other persons wasting time and money in the same direction.

(1.) Our first effort to decrease changes of temperature on the fine-clock was to put it into a double case, with cotton stuffing between the two cases. The fault of this was, that the passage of air was prevented and the clock-works became covered with mildew. No doubt the passage of air would have facilitated the changes of temperature we were anxious to guard against—but some passage of air seems absolutely necessary as an anti-mildew—and to render it as innocuous as possible to the temperature of the interior, the containing walls should be of as large size and mass as possible.

The degree of protection from changes of temperature, given by our present mere dark, wooden closets, may be studied in Plate 9, also in the Report to the Board of Visitors for 1870, and in the Table at the end of this section on the Transit Clock. The degree of protection that *would* be given were the closets constructed with stone walls, 3, 6, 12 and 24 French feet thick, may be approximately gathered from the Plates 1 and 2, showing the readings of thermometers at these depths in the rock of the hill; also from Plates 11 to 15, and the Section on the Earth thermometers; but the maximum protection from temperature-variations ever obtained by man is undoubtedly that of the King's Chamber in the Great Pyramid; with a minimum thickness of masonry of nearly 180 feet all round about it,—and with the reservation of two fine-bored air channels (or the diameter about $\frac{1}{250}$th of the length) on either side, at different angles, to permit the necessary exchange of air.

(2.) Besides labouring to procure a climate of as equable a temperature as possible with our limited means for the Sidereal Governing Clock, I also endeavoured to furnish it with the best compensation pendulum; and having had a powerful account given to me by that veteran chief of Practical Astronomy in Russia, the late F. G. W. Struve, of the method established in the Pulkova Observatory, of replacing the quicksilver, by a species of zinc and steel "grid-iron" pendulums made in the Observatory—I purchased

Digitized by Google

one of the latter, and tried it in our Sidereal Governing Clock (by Dent of London, and presented by Sir T. Brisbane) for several years—but, I regret to say, with so little satisfaction that the quicksilver and steel pendulum had to be restored in the end.

The compensation for temperature is now so close, that the next step should be, if possible, either to compensate or equalize the effect of changes of Barometric pressure.

(3.) The earliest contact springs furnished to us on adopting Jones' system of controlling, were placed on the pendulum near the top; but we were actually obliged to alter them to contacts made by the wheel-work, before the clock went sensibly as well while making electric-contacts as when it was entirely free.

(4.) The great turret clock came here with a dead-beat escapement, and the action of that, or the mere sound-accident accompanying its going, was its only method, as with clocks in general, of beating the seconds. Such beat was indeed much louder in that great clock than in any ordinary clock, but dull and slumberous. Mr Ritchie, therefore, was the first to propose to use a silent escapement and make the clock work a special hammer for the sole purpose of beating the seconds. This enabled a construction to be introduced giving greater velocity, and with that a higher note, to the striking part.

(5.) The silent escapement used in this case was Mr Denison's gravity and fan-fly escapement; eventually altered by Mr Ritchie to a gravity and heavy fly-wheel escapement as the only way, and in the end a most effective one, of equalizing the intervals of adjacent seconds beats.

(6.) The striking of the seconds by a hammer worked by the clock was first performed inside the clock, and the sound was brought out by a wooden tube. But eventually, on account of the residual noise of working the escapement—while the latter was still shut inside the clock, the hammer for seconds striking was brought outside the clock and now beats in the open air clearly and without any hindrance.

(7.) A gravity hammer, or one whose force is chiefly that of a falling body, was found to give a double or confused knock; but when the impulse to it was given by a spring greatly preponderating the weight, the blow became single and clear. Now therefore the hammer-head and its shaft are made very light, but a strong back pressure of a steel spring is applied. Such hammer is worked as a tilt-hammer by a little star-wheel moved by the clock, and the head remains continually in contact with the anvil or sounding board except when tossed up for one of its quick spring-blows.

(8.) The so-called hammer, being necessarily a miniature apparatus, had to be humoured by finding out on what sort of substance, shape, or thing its blow could produce the loudest and best sound. Generally the principle was ascertained, that—1st, the lighter the hammer the thinner must the material be; and 2d, the larger the area, the lower the resulting note. After trying many varied forms both larger and smaller, we are now using a wooden tambourine, 5 inches square as to its sounding board, and 5 inches long as to its sides; these latter being of soft deal 0·5 inch thick, and the former of hard olive wood about 0·13 inch thick. The hammer strikes horizontally,

and the sounding board is therefore placed vertical, wherefore the open end of the tambourine is at once directed to the more distant part of the Observatory apartment.

(9.) The driving weight of the clock is 180 lbs., and it is wound up by hand once a day. The weight of the hammer head is probably a quarter of an oz. Av.; and the radial length of its handle 8 inches.

The diameter of the fly-wheel governor of the Clock's escapement is 4·2 inches, its weight is 4·8 oz. Av., and the number of turns it makes in a second is 0·5. Its motion is continuous—although the movements of all the other clock wheels are discontinuous, or set in motion and stopped again at every action of the escapement—and is brought about by a smooth pressure of the rim of a crown-wheel on the escapement axis against the surface of a smooth pinion on the fly-wheel's axis; such smooth edge of the large driving crown-wheel being cut out at certain places in such a manner that there is no contact between it and the pinion when the clock works are standing still, but only during the time of each advance being made.

(10.) After attaining the power of very loud beats with a brass head to the clock-hammer, we have tried, and eventually preferred, for quick, sharp and clear sounds, a head of the same small size, but made of hard wood and therefore very light.

(11.) The observing clock is now as effective a repeater and sounder forth of the seconds ticks of the Governing Sidereal Clock as we could desire; but that Governing Clock might be better. Its rate is evidently at times quickly and largely affected by variations of Barometric pressure, to check and counteract which it has absolutely nothing,—and residual temperature effects are evidently in existence also, besides other small variations appearing with time and very difficult to attribute with certainty to their acting causes. This is, however, only equivalent to saying, and reminding mechanical artists, that the subject of the most accurate possible time keepers is still an open question for invention and improvement.

(12.) The numerical observations employed in drawing the curves on Plate 9, and alluded to under head (1.), page xxxii, are contained in the following Table.

(a) Foggy. Stars tremulous. Observations indifferent. (b) Night cloudy.
(c) Rapper acting so badly, the observations were taken by the beats of the clock itself.
(d) Observations made by means of the clock. (e) Stars diffused and unsteady.

(a) Some water having got between the lenses of the object glass, it was taken out and cleaned twice betwixt 31st August and 6th September.

(b) All the observations of this night were taken on the beats of a very loud and peculiar electrical rapper formed of two tambourines, worked of course by the Transit Clock, but placed in the Dome as a central situation to the whole Observatory.

(c) Observations by Transit Clock without rapper.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1860; AND THEIR METHODS OF REDUCTION.

Pages 1 to 12 contain the Transit Observations of stars for 1860, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going very badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 15 observations of α Ursæ Minoris, above and below the Pole, in the year 1860, the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole,—

		s.	
Wire	I.	+ 16·624	Equatorial
...	II.	+ 8·400	
...	III.	− 0·034	
...	IV.	− 8·246	
...	V.	− 16·745	

These values, immaterially different from those of 1859, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 33′ 44″ and 88° 34′ 34″) the following quantities or those adopted to a declination of 88° 34′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m.	s.			Declination 88° 34′
Wire	I.	+ 11	4·82	+ n'' ×	·131	
...	II.	+ 5	35·86	+ n ×	·066	
...	III.	− 0	1·33			
...	IV.	− 5	29·70	− n ×	·065	
...	V.	− 11	9·69	− n ×	·131	

and for δ Ursæ Minoris (whose Declination varied between 86° 35′ 42″ and 86° 36′ 23″) the following quantities, or those adapted to a declination of 86° 36′,

with the amount of alterations due to each additional second of Declination added under the term n'',—

			m.	s.		s.		s.	
Wire	I.	+	4	40·32	+	n	×	·023	Declination 86° 36′
...	II.	+	2	21·66	+	n	×	·012	
...	III.	−	0	0·62					
...	IV.	−	2	19·06	−	n	×	·012	
...	V.	−	4	42·36	−	n	×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$= \frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—0s·012, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is mechanically positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is mechanically positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head, and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} \ast - \text{R.A. 2d} \ast - (\text{obs. tr. 1st} \ast - \text{obs. tr. 2d} \ast) - \text{clock's loss in the interval}}{\left(\dfrac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}} \text{1st} \ast\right) - \left(\dfrac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}} \text{2d} \ast\right)}$$

In the course of the year 29 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

Digitized by Google

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\text{cos Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} = \frac{\text{sin Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1859, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1860.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined from the observed transits of the stars in the foregoing Table (excepting the close Polar stars), the correction of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used as much by themselves as with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

(f)	....

(a) Put the Clock's minute hand forward 1 minute.
(b) The electrical "rapper" for sounding the seconds of the clock loudly not acting well.
(c) A Pulkova-pendulum, or grid-iron pendulum of zinc and steel, made by M. Brauer, instrumental artist in the Imperial Russian Observatory at Pulkova, and highly approved of there for its compensating action during large and rapid variations of temperature, was applied to the Brisbane-Clock during this month in place of the steel and mercurial pendulum by Dent. Experiments with the electrical rapper still going on.
(d) Adjusted Pendulum for rate.
(e) A new contact maker applied to the Transit Clock.
(f) The value of all the subsequent observations of this year destroyed by the violently bad rates of the Clock; caused apparently by want of temperature compensation. Altered the amount of such compensation frequently by shifting the pins in the rods of steel and zinc.

(a) Wind increasing to a storm. (b) The month of June was occupied in making certain important alterations on the illumination-micrometer and other parts of the Mural Circle, as fully detailed in the "Explanation of Mural Circle Observations." (c) Observed smaller of two stars of 7·5 and 10 magnitudes. (d) The following of two stars in field. (e) Thin clouds. (f) Almost invisible at time of transit.

(a) Following. (b) Wind blowing in gusts, and increasing rapidly. (c) In the course of this day, an examination was successfully made, of the collimation error in Right Ascension of the Mural Circle, *per se*, or without introduction of either the level, or azimuth, errors,—by means of two temporary collimating telescopes on horizontal axes North and South of the Circle and specially prepared for the occasion. The error was found to be very small, or within the range usually allowed for a Meridian bisection, and quite insensible in its effects on the N. P. D. of the star observed. (d) Preceding.

(a) Scarcely seen at time of transit. (b) 8 standard stars were observed in R.A. this evening at various Polar Distances, to test the Meridian error of the circle's path, and they all agreed together within 1·1 sec. excepting a near Polar one. (c) Aurora towards the N.W.

MURAL CIRCLE OBSERVATIONS IN 1860.

The observations with the Mural Circle in 1860 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue, in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection, previous to June was performed simply by a single spider-line placed on the image of the star, but subsequently to that date, by bringing the stellar image between two parallel lines about 7 seconds of space apart: such line or lines being illuminated in a dark field.

Between the end of May and beginning of June extensive cleanings with repairs and alterations of small parts were performed upon the Mural Circle, and included the following items, as entered in a note-book at the time,—

(1.) Took down fixed stage, and slid circle out from pier, cleaned bearings, axle, &c., put in fresh oil.

(2.) Took out the telescope from circle, and cleaned its special axis of occasional movement.

(3.) Improved the illumination, by making one gas-light illuminate the Clock, both Microscopes A, B, and the wires of the telescope also; the latter by means of a tin tube attached to telescope, receiving light on a diagonal reflector at centre of circle, and conducting it down the tube to another reflector near the eye-end which throws it on the spider-threads, and illumines them so strongly that they are visible by reflexion in the Mercury trough, and can be used there for obtaining the nadir-point with the same eye-piece and illumination wherewith the stars are observed direct in the sky.

(4.) A diagonal prism is now adapted to end of eye-piece to allow of observations at *all* angles of altitude being taken by an observer looking in *one* constant angular direction; *i.e.*, horizontally and towards the west.

(5.) A wooden arm 8 feet long is fixed centrically across circle by soft

Digitized by Google

attachment to its spokes, to enable the observer more easily and safely to move the circle approximately, and bring the star sufficiently near the spider-line to be bisected by the Micrometer screw.

(6.) The size of the Mercury trough is increased from 5 × 7 to 10 × 11 inches, and 17 pounds more mercury added.

(7.) The heads of Micrometers both of the telescope and of Microscopes A and B are ratched so as to show by feel when they are being turned so as to *increase the readings;* the last movement in making any observations being directed to be always made in that manner.

(8.) In place of merely one vertical wire, or spider-line, as before, there are now two vertical wires to mark the Meridian, one on either side of it and about 6·5 seconds of time apart, for a star near the equator, and every star is only to be observed when crossing *between* these vertical and parallel wires. While in addition to the one horizontal wire for bisecting a star, there is, at a distance of about 20″ below it, a pair of horizontal wires 7 seconds apart in Polar distance, and between which a star is to be brought for Polar distance observation; such method being thought for small stars more exact than bisection, which often implies eclipsing or occulting, them by a single wire.

(9.) The Micrometer frame is remade in gun-metal, of unusual strength and stiffness, and with its central aperture, to be spanned by the spider-threads, only 0·6 inch in diameter, so as to reduce the flexure of these fiducial lines to a minimum; while the object-glass is now fastened into its cell, and the cell portions are closed on each other with chemical as well as mechanical fixings. Transits of standard stars were observed in September to test the Meridian error of the Circle's path as shown by the middle space between the two vertical wires, and it was found to be very small.

The same general principles of observations as before have been kept up since with these improved details. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time, and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

TABLE I.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious forms; the Latitude of the Observatory has been assumed as in former years = 55° 57′ 23″·2; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 46 to 53.

(a) Double. (b) Following of two stars of 7th and 8th magnitudes. (c) Double. (d) Definition very bad. Stars diffused and tremulous. (e) Evidences from the clock errors this night of either a change in the clock rate during 4 hours, or a change in the position of the Transit axis: suspect the latter.

(a) An apparent alteration of the rate during the hours of observation; probably owing to a swerving of the instrument through temperature.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1861; AND THEIR METHODS OF REDUCTION.

Pages 69 to 84 contain the Transit Observations of stars for 1861, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 5 observations of α Ursæ Minoris, above and below the Pole, in the year 1861, the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole,—

		s	
Wire	I.	+ 16·648	Equatorial
...	II.	+ 8·409	
...	III.	− 0·060	
...	IV.	− 8·243	
...	V.	− 16·756	

These values, immaterially different from those of 1860, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 34′ 3″ and 88° 34′ 53″) the following quantities or those adapted to a declination of 88° 34′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m. s.	s	
Wire	I.	+ 11 5·80	+ n × ·131	Declination 88° 34′
...	II.	+ 5 36·20	+ n × ·066	
...	III.	− 0 2·40		
...	IV.	− 5 29·58	− n × ·065	
...	V.	− 11 10·13	− n × ·131	

and for δ Ursæ Minoris (whose Declination varied between 86° 35′ 46″ and 86° 36′ 27″) the following quantities, or those adapted to a declination of 86° 36′,

with the amount of alteration due to each additional second of Declination added under the term n'',—

			m.	s.		s.		s.	
Wire	I.	+	4	40·73	+	n	×	·023	Declination 86° 36
...	II.	+	2	21·76	+	n	×	·012	
...	III.	−	0	1·01					
...	IV.	−	2	19·00	−	n	×	·012	
...	V.	−	4	42·56	−	n	×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$= \frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—$0^s{\cdot}012$, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} * - \text{R.A. 2d} * - (\text{obs. tr. 1st} * - \text{obs. tr. 2d} *) - \text{clock's loss in the interval}}{\left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} *\right) - \left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} *\right)}$$

In the course of the year 25 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\text{sin Star's North Polar Distance,}}$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\text{cos Star's Zenith Distance South}}{\text{sin Star's North Polar Distance,}}$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} \times \frac{\text{sin Star's Zenith Distance South}}{\text{sin Star's North Polar Distance,}}$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1861, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1861.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined

from the observed transits of the stars in the foregoing Table (excepting the close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.

Date.	Clock's Correction.	Date.	Clock's Correction.	Date.	Clock's Correction.	Date.	Clock's Correction.	Date.	Clock's Correction.

(a) Observing Clock being upwards of 6 minutes slow, the observations were taken by the old Transit Clock. (b) In consequence of the falling of a mass of snow on Micrometer A. when opening one of the top shutters, the moveable wires of the micrometer were broken, and the microscope otherwise injured. The microscope was removed to be repaired on the 23d and replaced on the 29th. (c) Observations made by Prof. Smyth.

MURAL CIRCLE OBSERVATIONS IN 1861.

The observations with the Mural Circle in 1861 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue, in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection being performed by bringing the stellar image between two parallel lines about 7 seconds of space apart: the lines being illuminated in a dark field.

The same general principles of observation as in former years have been kept up with improved details described in 1860. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time; and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious forms; the Latitude of the Observatory has been assumed as in former years $= 55° 57' 23''\cdot 2$; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 113 to 118.

ROYAL OBSERVATORY, EDINBURGH.

Individual Observations of Mean Right Ascensions of the Stars observed at the Royal Observatory, Edinburgh, in the Year 1862, reduced to January 1, 1862.

Date. Month and Day.	Date. Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1862.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1862; AND THE METHODS OF THEIR REDUCTION.

Pages 131 to 156 contain the Transit Observations of stars for 1862, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 10 observations of α Ursæ Minoris, above and below the Pole, in the year 1862, the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole,-

		s.	
Wire	I.	+ 16·636	Equatorial
...	II.	+ 8·414	
...	III.	− 0·068	
...	IV.	− 8·232	
...	V.	− 16·750	

These values, immaterially different from those of 1861, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 34′ 21″ and 88° 35′ 11″) the following quantities or those adapted to a declination of 88° 34′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m.	s.		s.
Wire	I.	+ 11	5·32	+ n ×	·131
...	II.	+ 5	36·44	+ n ×	·066
...	III.	− 0	2·72		
...	IV.	− 5	29·14	− n ×	·065
...	V.	− 11	9·89	− n ×	·131

Declination 88° 34′

and for δ Ursæ Minoris (whose Declination varied between 86° 35′ 51″ and 86° 36′ 32″) the following quantities, or those adapted to a declination of 86° 36′,

with the amount of alteration due to each additional second of Declination added under the term n'',—

			m.	s.				s.	
Wire	I.	+	4	40·52	+	n''	×	·023	Declination 86° 36′
...	II.	+	2	21·82	+	n	×	·012	
...	III.	−	0	1·14					
...	IV.	−	2	18·79	−	n	×	·012	
...	V.	−	4	42·44	−	n	×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$= \frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation, of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—0^s·012, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} \ast - \text{R.A. 2d} \ast - (\text{obs. tr. 1st} \ast - \text{obs. tr. 2d} \ast) - \text{clock's loss in the interval}}{\left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} \ast\right) - \left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} \ast\right)}$$

In the course of the year 35 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\cos \text{Star's Zenith Distance South}}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} \times \frac{\sin \text{Star's Zenith Distance South}}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1862, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1862.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined

from the observed transits of the stars in the foregoing Table (excepting the close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.

(a) Stars blurred.

(b) { •c •d •b •a •e } a observed ;—called a Nebula in B.A.C.

(c) Halo round the Moon.

(d) Sky getting overcast.

EXPLANATION OF THE MURAL CIRCLE OBSERVATIONS IN 1862.

The observations with the Mural Circle in 1862 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue, in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection being performed by bringing the stellar image between two parallel lines about 7 seconds of space apart: the lines being illuminated in a dark field.

The same general principles of observation as in former years have been kept up with improved details described in 1860. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time; and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious form; the Latitude of the Observatory has been assumed as in former years $=55° 57' 23''·2$; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 202 to 210.

(a) Definition very bad. (b) An inversion of clock rate during time of observation.
(c) Apparent inversion of clock rate during observation, probably caused by swerving of the piers under temperature.
(d) No clearly perceptible clock rate this night during the observations, probably from swerving of the piers from temperature.

(a) Very faint. (b) From this date to June 23rd experiments were tried on the rate of the clock by heating up the clock closet by means of gas, and occasionally oil lamps. (c) An inversion of the clock rate apparently during observation.

ROYAL OBSERVATORY, EDINBURGH.

INDIVIDUAL OBSERVATIONS OF MEAN RIGHT ASCENSIONS OF THE STARS OBSERVED AT THE ROYAL OBSERVATORY, EDINBURGH, IN THE YEAR 1863, REDUCED TO JANUARY 1, 1863.

B.A.C. 4, α Andromedæ.

Date: Month and Day.	Date: Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1863.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1863; AND THE METHODS OF THEIR REDUCTION.

Pages 228 to 256 contain the Transit Observations of stars for 1863, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 18 observations of α Ursæ Minoris, above and below the Pole, in the year 1863, the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole, and the period from Dec. 24, 1863, to the end of the year being excluded, Wire V. being then broken,—

		s	
Wire	I.	+ 16·660	Equatorial
...	II.	+ 8·408	
...	III.	− 0·072	
...	IV.	− 8·256	
...	V.	− 16·740	

These values, immaterially different from those of 1862, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 34′ 39″ and 88° 35′ 28″) the following quantities or those adapted to a declination of 88° 34′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m	s	s	s	
Wire	I.	+ 11	6·30	+ n ×	·131	Declination 88° 34′
...	II.	+ 5	36·17	+ n ×	·066	
...	III.	− 0	2·88			
...	IV.	− 5	30·10	− n ×	·065	
...	V.	− 11	9·50	− n ×	·131	

and for δ Ursæ Minoris (whose Declination varied between 86° 35′ 56″ and

Digitized by Google

86° 36′ 36″) the following quantities, or those adapted to a declination of 86° 36′, with the amount of alteration due to each additional second of Declination added under the term n'', –

			m.	s.		"		s.	
Wire	I.	+	4	40·93	+	n	×	·023	Declination 86° 36′
...	II.	+	2	21·76	+	n	×	·012	
...	III.	–	0	1·20					
...	IV.	–	2	19·22	–	n	×	·012	
...	V.	–	4	42·27	–	n	×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$-\frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—0^s·012, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} * - \text{R.A. 2d} * - (\text{obs. tr. 1st} * - \text{obs. tr. 2d} *) - \text{clock's loss in the interval}}{\left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} *\right) - \left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} *\right)}$$

In the course of the year 35 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

TABLE I.

Adopted Instrumental Corrections, expressed in Seconds of Time for convenience of application to Time Observations.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\text{cos Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} = \frac{\text{sin Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1863, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1863.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined

Digitized by Google

from the observed transits of the stars in the foregoing Table (excepting the close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.

(a) Aurora near horizon. (b) Illumination of wires in eye-piece to-night very defective.

(c) Examined illumination apparatus, thoroughly cleaned all the internal tubes, reflectors, &c., &c., and replaced all parts both of eye-piece and tin-light tubes, between gas light on stage and eye-end of telescope-tube carrying the wires which were by no means disturbed.—C. P. S. Nov. 9, 1863. (d) Good definition.

EXPLANATIONS OF THE MURAL CIRCLE OBSERVATIONS IN 1863.

The observations with the Mural Circle in 1863 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection being performed by bringing the stellar image between two parallel lines about 7 seconds of space apart: the lines being illuminated in a dark field.

The same general principles of observation as in former years have been kept up with improved details described in 1860. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time; and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

Digitized by Google

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious forms; the Latitude of the Observatory has been assumed as in former years $=55° \; 57' \; 23''{\cdot}2$; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 305 to 313.

(a) Hazy. Bad definition.

(b) Two stars in field observed following. Difference R. A. 5 secs.

(c) Very faint.

29	0·99			41·64

B.A.C. 1703.

Month and Day	Fraction of Year	Magnitude	N.P.D.	Mean R.A.
Jan. 5	0·01	7·0	73 40	5 20 19·66

B.A.C. 1730, δ Orionis.

Month and Day	Fraction of Year	Magnitude	N.P.D.	Mean R.A.
Jan. 2	0·00	(2·0)	90 24	5 25 3·60
7	0·02			3·54
17	[illegible]·04			3·46
Dec. 21	0·97			3·50
29	0·99			3·53

B.A.C. 1765, ι Orionis.

Date: Month and Day.	Date: Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1864.
Jan. 2	0·00	(2·5)	91° 17′	5h 29m 18s·50
5	0·01			18·71
7	0·02			18·86
17	0·04			18·84
Dec. 21	0·97			18·72
29	0·99			18·75
30	1·00			18·70

B.A.C. 1883, α Orionis.

Date: Month and Day.	Date: Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1864.
Jan. 2	0·00	(1·0)	82 37	5 47 48·54
4	0·01			48·61
5	0·01			48·62
7	0·02			48·58
17	0·04			48·56
19	0·05			48·53
23	0·06			48·53
Dec. 21	0·97			48·61
30	1·00			48·47

B.A.C. 1958, ν Orionis.

Date: Month and Day.	Date: Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1864.
Jan. 19	0·05	(4·5)	75 13	5 59 48·50
23	0·06			48·41
27	0·07			48·41
Feb. 5	0·10			48·40
Dec. 30	1·00			48·47

B.A.C. 2163, γ Geminorum.

Date: Month and Day.	Date: Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1864.
Jan. 4	0·01	(2·5)	73 29	6 29 51·36
5	0·01			51·31
23	0·06			51·30

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1864; AND THE METHODS OF THEIR REDUCTION.

Pages 330 to 352 contain the Transit Observations of stars for 1864, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 17 observations of α Ursæ Minoris, above and below the Pole, in the year 1864, (and after January of that year when, in order to replace Wire V. broken a few days before, the whole system of wires was renewed), the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole.

		s.	
Wire	I.	+ 16·584	Equatorial
...	II.	+ 8·345	
...	III.	− 0·087	
...	IV.	− 8·316	
...	V.	− 16·525	

These values, sensibly different from those of 1863, as belonging to a different set of wires, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 34′ 56″ and 88° 35′ 45″) the following quantities or those adapted to a declination of 88° 35′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m.	s.	s.	s.	
Wire	I.	+ 11	11·06	+ n ×	·133	Declination 88° 35′
...	II.	+ 5	37·57	+ n ×	·067	
...	III.	− 0	3·53			
...	IV.	− 5	36·40	− n ×	·067	
...	V.	− 11	8·70	− n ×	·132	

and for δ Ursæ Minoris (whose Declination varied between 86° 36′ 0″) and

86° 36′ 40″) the following quantities, or those adapted to a declination of 86° 36′, with the amount of alteration due to each additional second of Declination added under the term n'',—

			m.	s.				s.	
Wire	I.	+	4	39·65	+	n''	×	·023	Declination 86° 36′
...	II.	+	2	20·71	+	n	×	·012	
...	III.	−	0	1·48					
...	IV.	−	2	20·21	−	n	×	·012	
...	V.	−	4	38·66	−	n	×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$= \frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—0^s·012, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

Digitized

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made :—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} \ast - \text{R.A. 2d} \ast - (\text{obs. tr. 1st} \ast - \text{obs. tr. 2d} \ast) - \text{clock's loss in the interval}}{\left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} \ast\right) - \left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} \ast\right)}$$

In the course of the year 31 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\text{cos Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} = \frac{\text{sin Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1864, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1864.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined from the observed transits of the stars in the foregoing Table (excepting the

close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.

EXPLANATIONS OF THE MURAL CIRCLE OBSERVATIONS IN 1864.

The observations with the Mural Circle in 1864 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection being performed by bringing the stellar image between two parallel lines about 7 seconds of space apart: the lines being illuminated in a dark field.

The same general principles of observation as in former years have been kept up with improved details described in 1860. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time; and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

TABLE I.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious forms; the Latitude of the Observatory has been assumed as in former years $=55° 57' 23''·2$; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 394 to 402.

ROYAL OBSERVATORY, EDINBURGH.

(a) Faint. Overcast.

(b) An apparent inversion of the clock's rate during the time of observation, caused most probably by a swerving of the instrument piers through temperature.

ROYAL OBSERVATORY, EDINBURGH.

Individual Observations of Mean Right Ascensions of Stars observed at the Royal Observatory, Edinburgh, in the Year 1865, reduced to January 1, 1865.

Date. Month and Day.	Date. Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1865.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1865; AND THE METHODS OF THEIR REDUCTION.

Pages 418 to 433 contain the Transit Observations of stars for 1865, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Intervals of the Wires.

From 28 observations of α Ursæ Minoris, above and below the Pole, in the year 1865, the intervals of the wires and their Equatorial distances from their mean or middle point were found to be, the star being above the Pole.

		s.	
Wire	I.	+ 16·590	Equatorial
...	II.	+ 8·365	
...	III.	− 0·106	
...	IV.	− 8·301	
...	V.	− 16·528	

These values, immaterially different from those of 1864, have been employed in the reductions throughout the year; using for Polaris (whose Declination varied between 88° 35′ 13″ and 88° 36′ 2″) the following quantities or those adapted to a declination of 88° 35′, with the amount of alteration due to each additional second of Declination added under the term n'',—

		m.	s.	s.		s.	
Wire	I.	+ 11	11·30	+ n	×	·133	Declination 88° 35′
...	II.	+ 5	38·38	+ n	×	·067	
...	III.	− 0	4·29				
...	IV.	− 5	35·92	− n	×	·067	
...	V.	− 11	8·80	− n	×	·132	

and for δ Ursæ Minoris (whose Declination varied between 86° 36′ 3″) and 86° 36′ 43″) the following quantities, or those adapted to a declination of 86° 36′.

with the amount of alteration due to each additional second of Declination added under the term n'',—

$$\left.\begin{array}{llrrrl} & & & \text{m.} & \text{s.} & \qquad\qquad\text{s.} \\ \text{Wire} & \text{I.} & + & 4 & 39{\cdot}76 & + \; n'' \times {\cdot}023 \\ \cdots & \text{II.} & + & 2 & 21{\cdot}04 & + \; n \times {\cdot}012 \\ \cdots & \text{III.} & - & 0 & 1{\cdot}79 & \\ \cdots & \text{IV.} & - & 2 & 20{\cdot}02 & - \; n \times {\cdot}012 \\ \cdots & \text{V.} & - & 4 & 38{\cdot}70 & - \; n \times {\cdot}023 \end{array}\right\} \text{Declination } 86^\circ\ 36'$$

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small, being

$$= \frac{\text{Sum of Equatorial intervals for the Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Stars N.P.D.},$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc.*

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—$0^s{\cdot}012$, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} \ast - \text{R.A. 2d} \ast - (\text{obs. tr. 1st} \ast - \text{obs. tr. 2d} \ast) - \text{clock's loss in the interval}}{\left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} \ast\right) - \left(\frac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} \ast\right)}$$

In the course of the year 40 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\text{cos Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} \times \frac{\text{sin Star's Zenith Distance South}}{\text{sin Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

Correction of the Clock.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1865, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1865.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined from the observed transits of the stars in the foregoing Table (excepting the

close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.

EXPLANATIONS OF THE MURAL CIRCLE OBSERVATIONS IN 1865.

The observations with the Mural Circle in 1865 were taken by Mr Peter Williamson, Second Assistant Astronomer, under the supervision of the Astronomer.

The subjects observed were chiefly stars remarkable for proper motion. They are designated as far as possible by the number in the British Association Catalogue in col. 2, and by proper name or description in col. 3, assisted if necessary by notes at the foot of the page, as well as by approximate estimate of the magnitude in col. 4, and time of transit past centre of field (by an uncorrected sidereal journeyman clock, but showing fairly differences from star to star) in col. 5.

In Polar distance the star was always carefully bisected when crossing the centre of the field, either at the precise instant if its motion was steady, or in its mean path through several seconds if unsteady or undulatory, as was too often the case. Such bisection being performed by bringing the stellar image between two parallel lines about 7 seconds of space apart: the lines being illuminated in a dark field.

The same general principles of observation as in former years have been kept up with improved details described in 1860. The completion of every observation therefore in Polar distance still depends largely on the Telescope micrometer, whose numbers are a necessary addition to the readings both of the Pointer on the Limb of the Circle and of the two horizontal Microscopes A, B; all which numerical particulars are given in columns 6, 7, 8, and 9.

In columns 10 and 12, the readings of the Barometer and exterior thermometer are noted for refraction purposes: the interior thermometer being assumed to be practically the same as the exterior, for all star-observations when a thorough draught was kept up through the observing room, as was always the case during star observations. During observations for the Nadir-point, on the contrary, all shutters and windows were closed to prevent disturbance to the mercury, and then a sensible difference between the thermometers usually occurred, and is shown by the figures in the narrow column 11, compared with those in column 12.

Columns 13, 14, and 15 contain various points connected with the meteorologic and other circumstances of the observations, as they appeared to the observer at the time; and column 16 contains the reduction of the angular observations in columns 6 to 9, to the stage of "Apparent Zenith Distance South."

To this end, the readings of the Microscopes have been corrected for the error of their runs, as ascertained over 5′ spaces on the limb of the Circle, with the telescope directed first to the Zenith and then to the Nadir: also for the difference between the mean of two and the mean of six Microscopes as ascertained by examination in 1855 (see p. 76, vol. xii.); also for the Telescope micrometer readings converted into arc on the estimate of one revolution being equal to 27·704″, as ascertained by observations in the Mercury trough with the collimating eye-piece, combined with readings of all the six circumferential Microscopes. The Circle positions are then converted into Apparent Zenith Distances, by the application of a reading for the Zenith point derived from observation of the Nadir, as shown by making the bisecting wire cover its illuminated image in the Mercury trough, an observation made generally both at the beginning and conclusion of every series of star measures. The chief data of these several corrections are contained in the following Tables I., II., and III.

For the remaining reductions, the refractions have been computed by Bessel's Table, as represented in the Rev. R. Sheepshank's compendious forms; the Latitude of the Observatory has been assumed as in former years $=55° 57' 23''·2$; and the *Apparent* N. Polar Distances on the day of observation have been converted into *Mean* North Polar Distances for the beginning of the

year of observation, by applying the corrections for precession, nutation, aberration, and proper motions, taken from the elements and subsidiary tables given in the Nautical Almanac and the British Association Catalogue; and whose sum is represented in the last column of each observation-page. The individual results for magnitude and place of each star are collected on pp. 466 to 472.

(a) The clock errors this night shew that apparent change in the rate of the clock, which occurs so often, but is caused most probably in truth by the swerving of the piers carrying the Transit Instrument, on account of change of temperature. (b) Cloudy. (c) Very unsteady. Bad observation.

(a) Definition very bad. (b) Definition bad. (c) This night's clock errors are another striking example of fictitious change of clock-rate produced really by temperature-swerving of the piers carrying the Transit Instrument.

(a) Faint.
(c) Bad definition.
(b) July 14.—Mr Adie removed Transit Micrometer, and put in a new set of Wires. Returned July 19th.
(d) Definition very bad.

(a) Another of these perplexing cases of apparent change of clock-rate, but caused really by temperature swerving the piers of the Transit Instrument.
(b) Bad definition.

(a) Very faint. (b) Definition very bad all night.
(c) A marked case of a fictitious change in the clock's rate, produced most probably by temperature swerving the piers of the Transit Instrument.

ROYAL OBSERVATORY, EDINBURGH.

Individual Observations of Mean Right Ascensions of Stars observed at the Royal Observatory, Edinburgh, in the Year 1866, reduced to January 1, 1866.

Date. Month and Day.	Date. Fraction of Year.	Magnitude observed.	Approximate North Polar Distance.	Mean Right Ascension, January 1, 1866.

EXPLANATION OF THE EDINBURGH TRANSIT OBSERVATIONS FOR 1866; AND THE METHODS OF THEIR REDUCTION.

Pages 485 to 502 contain the Transit Observations of stars for 1866, similarly with those for 1849, where the methods of reduction are more fully described; the variable data for the present year being as below.

The star observations were taken almost wholly by Mr Alexander Wallace, M.A., the First Assistant Astronomer. They were actually more numerous than here recorded, because, with a view chiefly to economy in printing, all days of observation with less than four standard stars have been struck out; also parts of a day far removed from the chief observing hours of the night; also those periods of the year when either the Instrumental corrections were uncertain, or the Clock going badly. The said observations, however, had been already computed in our MS. books, and have often served useful temporary purposes, as for approximate clock-corrections and instrumental errors.

The Micrometer observations for instrumental corrections have, on the other hand, always been taken by the Astronomer, and he has also decided on the quantities for computation to be adopted for each day of star observation.

Correction of Wires for 1866.—No. 1.

In this year 1866, the system of wires was renewed on July 19; and the new wires (*i.e.* spider-lines) were by no means exactly replaced on the traces of their predecessors. We take therefore first the period of January 1 to July 18, 1866. For that period, from 6 observations of α Ursæ Minoris, the intervals of the wires and their Equatorial distances from the Mean or Middle point were found to be, the star being above the Pole,—

January 1 to July 18, 1866	Wire	I.	+ 16·580 s.	Equatorial
	...	II.	+ 8·364	
	...	III.	− 0·124	
	...	IV.	− 8·297	
	...	V.	− 16·524	

These values, immaterially different from those of 1865, have been employed in the reductions from January 1 to July 18, 1866; using for Polaris (whose Declination varied from 88° 35′ 30″ to 88° 36′ 18″) the following quantities or those adapted to a declination of 88° 35′, with the amount of alteration due to each additional second of Declination added under the term of n'',—

January 1 to July 18, 1866	Wire	I.	+ 11 m. 10·89 s. + n'' × ·133 s.	Declination 88° 35′
	...	II.	+ 5 38·36 + n × ·067	
	...	III.	− 0 5·03	
	...	IV.	− 5 35·64 − n × ·067	
	...	V.	− 11 8·62 − n × ·132	

and for δ Ursæ Minoris (whose Declination varied from 86° 36′ 6″ to 86° 36′ 45″) the following quantities or those adapted to a declination of 86° 36′, with the amount of alteration due to each additional second of Declination added under the term of n'',—

			m.	s.		s.	
January 1 to July 18, 1866	Wire I.	+	4	39·58	+ n ×	·023	Declination 86° 36′
	... II.	+	2	21·02	+ n ×	·012	
	... III.	−	0	2·10			
	... IV.	−	2	19·90	− n ×	·012	
	... V.	−	4	38·63	− n ×	·023	

1866.—No. 2.

But for the period extending from July 19 to December 31, 1866, the intervals of the wires, from 5 observations of α Ursæ Minoris, and their Equatorial distances from the Mean or Middle point were found to be, the star being above the Pole,

		s.	
July 19 to December 31, 1866,	Wire I.	+ 16·516	Equatorial
	... II.	+ 8·206	
	... III.	− 0·676	
	... IV.	− 7·973	
	... V.	− 16·679	

These values, largely different from those of the preceding part of the year for the reasons already given, have been employed in the reductions from July 19 to December 31; using for Polaris (whose Declination varied from 88° 35′ 30″ to 88° 36′ 18″) the following quantities or those adapted to a declination of 88° 35′, with the amount of alteration due to each additional second of Declination added under the term of n'',

			m.	s.		s.	
July 19 to December 31, 1866	Wire I.	+	11	8·30	+ n ×	·133	Declination 88° 35′
	... II.	+	5	31·97	+ n ×	·065	
	... III.	−	0	2·83			
	... IV.	−	5	22·52	− n ×	·065	
	... V.	−	11	14·92	− n ×	·133	

and for δ Ursæ Minoris (whose Declination varied from 86° 36′ 6″ to 86° 36′ 45″) the following quantities or those adapted to a declination of 86° 36′, with the amount of alteration due to each additional second of Declination added under the term of n'',—

			m.	s.		s.	
July 19 to December 31, 1866	Wire I.	+	4	38·50	+ n ×	·023	Declination 86° 36′
	... II.	+	2	18·37	+ n ×	·012	
	... III.	−	0	1·18			
	... IV.	−	2	14·41	− n ×	·012	
	... V.	−	4	41·26	− n ×	·023	

The correction generally for the imperfect transit of a star, whose North Polar Distance is not very small,

$$= \frac{\text{Sum of Equatorial intervals for Wires observed}}{\text{Number of Wires}} \times \text{cosecant of Star's N. P. D.}$$

this quantity being applied to the mean of whatever wires were observed.

With close Polar stars, the *Sine* is used in place of the *Arc*.

The signs and order of the Wires are to be changed when the star is below the Pole.

In the column entitled "Reduction to the Mean of the Wires," either the simple arithmetical mean of the Wires—if 5 were observed—is entered; or, if a less number, the reduced mean according to the method already explained and the quantities above given.

CORRECTIONS FOR INSTRUMENTAL DEVIATIONS.

These deviations are three in number, and are severally termed, Collimation error, Level error, and Azimuth error.

The Collimation error is the deviation of the line joining the optical centre of the object-glass and the Mean of the Wires, from the plane perpendicular to the axis of rotation; and is *mechanically* positive, or is positive as a correction for all objects at all altitudes both above and below the horizon, when the object-glass deviates to the east of the said plane:—0^s·012, the diurnal aberration, is included, for practical convenience, in the sum representing the collimation.

The Level error is the angle of inclination of the axis of rotation to the horizon, measured in a vertical plane; and is *mechanically* positive, as a correction, for all objects above the horizon, negative for those below, when the Western end is higher than the other.

The Azimuthal error is the angle of deviation of the axis of rotation (presumed approximately horizontal) from the East and West line, measured in a horizontal plane; and is *mechanically* positive as a correction for all objects South of the Zenith, or Nadir, and negative for those North of the same, when the Western end of said axis deviates towards the South.

COLLIMATION AND LEVEL ERRORS.

These are determined, as explained in former years, by special observations made from time to time with the collimating eye-piece, and by measuring micrometrically the distance between the Middle wire and its reflected image in reversed positions of the transit-instrument's axis.

For dates between the epochs of observation, the errors have been assumed to vary as the time, except where the readings of the earth-thermometers, as noticed in the Introduction, have indicated a modification thereof to be probably desirable.

AZIMUTHAL ERROR.

Of the three usual methods for determining the azimuthal position of a transit-instrument; viz. by a Polar star combined with an Equatorial star, by two successive transits of a Polar star above and below the Pole, or by three consecutive transits of a Polar star, the first plan has alone been adopted; for although the two latter have the advantage of being independent of the Right Ascension assumed for the stars, yet they can only be employed with safety when the stability of the instrument can be depended on through the twelve or twenty-four hours during which the observations extend.

Now grave doubts had long existed on this head; and, as set forth both in the Introduction to this volume and the Report to the Board of Visitors for 1870, towards the end of the volume, see pp. R 50 to R 57, they have since been proved to be only too well founded. The following therefore is the formula which has always been adopted, enabling, for each transit of a Polar star observed, a comparatively instantaneous determination of the Azimuthal error then to be made:—

$$\text{Azimuthal error} = \frac{\text{R.A. 1st} \ast - \text{R.A. 2d} \ast - (\text{obs. tr. 1st} \ast - \text{obs. tr. 2d} \ast) - \text{clock's loss in the interval}}{\left(\dfrac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{1st} \ast\right) - \left(\dfrac{\sin \text{Z.D. South}}{\sin \text{N.P.D.}}\ \text{2d} \ast\right)}$$

In the course of the year 40 combinations of either α, or δ, Ursæ Minoris and a Clock star were obtained, from which the Azimuth error at these epochs was computed, and for dates between them the error was made to vary nearly as the time, modified in some cases by the temperature and the annual curve shown in Plate III.

TABLE I.

ADOPTED INSTRUMENTAL CORRECTIONS, EXPRESSED IN SECONDS OF TIME FOR CONVENIENCE OF APPLICATION TO TIME OBSERVATIONS.

The correction to the star observations of times of Transit, for each of the above three instrumental deviations successively, is,

$$\text{Collimation correction} \times \frac{1}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole.

$$\text{Level correction} \times \frac{\cos \text{Star's Zenith Distance South}}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole, and negative when it crosses the Meridian below the Pole. And

$$\text{Azimuthal correction} - \frac{\sin \text{Star's Zenith Distance South}}{\sin \text{Star's North Polar Distance}},$$

the sign being positive for a star above the Pole *and* to the South of the Zenith, also for a star below the Pole and North of the Zenith; but negative when above the Pole and to the North of the Zenith.

CORRECTION OF THE CLOCK.

For computing the errors of the Clock and the Azimuthal errors of the Transit Instrument, the following Table of the Mean Right Ascensions of the principal stars for January 1, 1866, has been employed, and was kindly communicated at the time by G. B. Airy, Esq., Astronomer Royal, as being the same employed by him for reducing the Greenwich Observations of 1866.

TABLE II.

The Mean Right Ascensions are converted into Apparent for any day of observation, by the application of the reductions of mean to apparent places taken from the Nautical Almanac. The Correction of the Clock is determined from the observed transits of the stars in the foregoing Table (excepting the

close Polar stars), the corrections of the instrument being previously applied, compared with the Apparent Right Ascensions computed.

The Corrections of the Clock thus determined are contained in the column entitled "Correction of Clock observed."

The sign + prefixed to the Correction of the Clock denotes that the clock is slow; the sign − that it is fast.

On account partly of the variability at times of the Clock-rate, and still more frequently of swerving in the azimuthal position of the Transit Instrument as produced by changes of temperature acting on its supporting stone piers during the observations, the "Adopted Clock Corrections" have been generally obtained by graphical projection, and the stars of each night have been used much more by themselves than with reference to those of preceding and following nights.

At the same time, to afford a tabular view, in the usual manner, of the march of the Clock, its daily errors at 0^h Sidereal Time, as given more or less approximately by the curves, are contained in the following Table.

TABLE III.

CORRECTION FOR TRANSIT CLOCK AT 0^h SIDEREAL TIME.
